Harveian Oration

Health in an unequal world

Michael Marmot

William Harvey and the Harveian Trust

William Harvey was born in Folkestone on April 1, 1578. He was educated at the King’s School, Canterbury, Gonville, and Caius College, Cambridge, and the University of Padua, graduating as doctor of arts and medicine in 1602. He became a Fellow of the Royal College of Physicians in 1607 and was appointed to the Lumleian lectureship in 1615.

In the cycles of his Lumleian lectures over the next 13 years, Harvey developed and refined his ideas about the circulation of the blood. He published his conclusions in 1628 in Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus, which marks the beginning of clinical science. In it, Harvey considered the structure of the heart, arteries, and veins with their valves. By carefully devised experiments and supported by the demonstration of the unidirectional flow of the blood in the superficial veins of his own forearm, he established that the blood circulated, and did not ebb and flow as had been believed for more than 1000 years.

Harvey was a great benefactor of the College. In 1656 he gave his patrimonial estate of Burmarsh (in Romney Marsh, Kent) to the College to provide for the annual oration and feast. In an indenture dated June 21, 1656, he directed that:

to the end friendship between the members of the said College may be the better continued and maintained, there shall be once every month at the meeting of the Censors at the said College some small collation provided...and once every year there shall be a general feast kept within the said College for all the Fellows that shall please to come...and on the day when such feast shall be kept some one person...shall make an oration...with an exhortation to the Fellows and Members of the said College to search and study out the secret of Nature by way of experiment; and also for the honour of the profession to continue mutual love and affection amongst themselves without which neither the dignity of the College can be preserved nor yet particular men receive that benefit by their admission into the College which else they might expect.

In poor countries, tragically, people die unnecessarily. In rich countries, too, the higher death rate of those in less fortunate social positions is unnecessary. Can there be a link between these two phenomena: inequalities in health between countries and inequalities within? Surely, we could argue, the depredations of grinding poverty— inadequate food, shelter, clean water, and basic medical care or public health—that ravage the lives of the poor in developing countries are different in kind from the way that social disadvantage leads to poor health in modern Britain, for example. The diseases of the slums of Nairobi are, to be sure, different in kind from the diseases that affect disadvantaged people in east London in the UK, or Harlem in the USA, and have different proximate causes.

There is, however, a link. The unnecessary disease and suffering of disadvantaged people, whether in poor countries or rich, is a result of the way we organise our affairs in society. I shall argue, in this oration, that failing
to meet the fundamental human needs of autonomy, empowerment, and human freedom is a potent cause of ill health. In making this case, I shall bring together two rather disparate streams of work. The first is a report of my own research endeavour. I have sought explanations for the social gradient in health, as observed in the Whitehall studies, pointing to the fundamental importance of the circumstances in which people live and work. I emphasise control and the opportunities for full social engagement. The second draws on the work of development economists Amartya Sen and Nicholas Stern. Sen suggests we should see development as freedom to lead the life people have reason to value. Stern’s concept of empowerment is close to Sen’s freedom. Without empowerment, argues Stern, economic growth will not bring improvements in health and education as well as relief from poverty.

Both in the case of the social gradient in health within countries and the differences in health among countries, changing social conditions to ensure that people have the freedom to lead lives they have reason to value would lead to marked reductions in health inequalities. In both cases the active involvement of individuals, and communities, in decisions that affect their lives is crucial.

Drawing attention to the central role of human freedoms in health is a statement of philosophical position and a call to social action. It is also based on a synthesis of a great deal of medical and social research. William Harvey, who established these orations, famously encouraged the orator to exhort the fellowship of this College to search out the secret of Nature by way of experiment. For an epidemiologist, of course, Nature herself provides the experiments—grand natural experiments. For this epidemiologist, Nature is in league with Society. Societies organise their affairs in different ways and these differences are the grand experiments that provide the researcher with the opportunity to search out the causes of health and disease. I make the connection between social conditions and biological pathways that plausibly provide the link to cardiovascular and other diseases. I do not stop at biology, however.

William Harvey said that the feast and oration should be not only to encourage scientific experiment but for the honour of the profession to continue mutual love and affection among themselves. Outside observers might feel that Fellows of the Royal College of Physicians need no further encouragement to indulge in mutual love. I will focus on the honour of the profession. Our profession seeks not only to understand but also to improve things. Some doctors feel queasy about the prospect of social action to improve health, which smacks of social engineering. Yet, a physician faced with a suffering patient has an obligation to make things better. If she sees 100 patients the obligation extends to all of them. And if a society is making people sick? We have a duty to do what we can to improve the public health and to reduce health inequalities in social groups where these are avoidable and hence inequitable or unfair. This duty is a moral obligation, a matter of social justice.

Because of this moral obligation, WHO set up a Commission on Social Determinants of Health, which I chair, that is seeking to reach evidence-based policy recommendations on what can be done to reduce health inequalities and improve the health of the disadvantaged. In bringing together research on the social gradient in health within countries and inequalities among countries, I am seeking to provide a clear intellectual justification for the Commission’s work.

In arguing that to control disease we need an understanding of disease mechanisms as well as social and political action, I have distinguished antecedents. If an appeal to authority be needed then Rudolph Virchow (1821–1902), whose biology has made appearances in these orations, will amply suffice.

A lesson in the importance of environment

As physicians we are trained that the patient comes first and last. Searching out individual causes of disease, however, does not negate the importance of environmental causes. Studies of migrants show that as environments change, disease rates change. I learnt this lesson through engagement with Leonard Syme and others in a study of men of Japanese ancestry, living in Japan, Hawaii, and California. As Japanese men migrate across the Pacific, the rate of coronary heart disease rises and the rate of stroke falls. Part of the reason lies with diet and its effect on plasma cholesterol. But my study, with Len Syme, of Japanese men in California showed a clear relation between degrees of acculturation and coronary heart disease rates—more Americanisation, more disease—that was independent of plasma cholesterol, blood pressure, or smoking. We had some evidence that the particular aspect of Japanese culture that was protective was the degree to which people remained within the protective confines of their ethnic group, thus benefiting from the social cohesion of Japanese culture.

Coming back to Britain, I studied the health of migrants to England and Wales. In general, migrants showed some persisting effects on disease patterns of the country from which they came and clear changes towards the disease patterns of the host country. The general point was that as people change their environment, disease rates change. Crucial to this changed environment seemed to be aspects of social relationships, which suggested that the way both to understand disease causation and to change the rates of disease was to pay attention to the social environment.

One thing led to another. Paying attention to the social environment led to the body of research summarised below and to collaboration with other key individuals in scientific enquiry on the relation of society to health. I am now involved in the process of trying to change these relations via the Commission on Social Determinants of Health.
Inequalities in health within societies

Social gradient in richer countries

My starting point is the Whitehall study of British civil servants. Figure 1 shows results from the 25-year mortality follow-up of men, originally aged 40–69, by age at death. The graded nature of the link between position in the hierarchy and death—the social gradient in mortality—is the challenge to understanding. The gradient is a broader issue than that of poverty and health. We have no difficulty in contemplating how dirty water, poor sanitary facilities, and inadequate nutrition and shelter could cause the diseases of poverty. But Whitehall is not Kibera (the shanty town in Nairobi that is home to 500 000 people). In Whitehall, we have clean water and bathrooms, an excess in supply of calories to eat, and shelter from the elements. Yet among these civil servants, none of whom were destitute, men second from the top of the occupational hierarchy had a higher rate of death than men at the top. Men third from the top had a higher rate of death than those second from the top. I have been writing about this gradient for 28 years and it has been at the core of my research agenda. Why, among men who are not poor in the usual sense of the word, should the risk of dying be intimately related to where they stand in the social hierarchy?

The Whitehall II study, launched 20 years after the first Whitehall study, extended the observation to women. Further, the gradient in mortality extended to most of the major causes of death. Most of our attempts at explanation have focused on cardiovascular disease because there has been such a large body of research on the biological pathways involved in coronary heart disease. The real puzzle is why there should be a social gradient in so many different causes of death.

The gradient is not confined to civil servants. I live and work in the London borough of Camden. In about 25 min I can cycle from Somers Town, just north of University College London, to Hampstead, a little way further north. The life expectancy gap between men living in these two areas is 11 years. I use the ends of the spectrum—the gap between top and bottom—to illustrate the size of the difference but we should always bear in mind that the phenomenon is a gradient: the population is ranged along the spectrum from life expectancy of 70 years for men in Somers Town and St Pancras to 81 years for men in Hampstead.

In Glasgow the gap is bigger. The difference in life expectancy between the most deprived and least deprived areas was 6·9 years in 1981–85; 20 years later this rate had increased to almost 12 years. In and around Washington DC, USA, the gap is bigger still. A 20-year gap exists between poor blacks in downtown Washington and well-off whites in Montgomery County, MD, a short metro ride away.

The differences in the USA draw attention to the need to clarify what we think lies behind the social gradient in health. Americans do not therefore record their vital statistics, as we have done for so long in the UK, by some measure of social class or socioeconomic group. By contrast, in the USA, statistics are traditionally recorded by race. There has been much discussion as to whether racial differences represent something more than socioeconomic differences; whether or not the whole story, socioeconomic differences, and the wider social environment are important in generating racial differences.

Robert Erikson used the Swedish Census, linked to mortality, and showed a remarkable social gradient in mortality. Men with a PhD had lower mortality rates than those with a master’s degree who, in turn, had lower rates than those with lower qualifications. Table 1 shows mortality rates for Indigenous and non-Indigenous peoples in Australia, Canada, and New Zealand.

Table 1: Life expectancy of indigenous peoples in Australia, Canada, and New Zealand.

mortality than those with a bachelor’s degree, and so on. The social gradient in mortality stretched from top to bottom of the social hierarchy.

The Whitehall and Swedish studies make clear that to understand inequalities in health we need to go beyond binary thinking: poverty bad, non-poverty good. Health follows the social gradient. The challenge is to understand how position in the social hierarchy is related to health. We need to go beyond material deprivation, but recognising the importance of the gradient should not lead us to ignore those at the bottom. Particularly egregious examples of the effects of social exclusion on health come from comparisons of health of indigenous peoples in Canada, New Zealand, and Australia, with that of the total population (table 1).

In each case, the gap between the indigenous group and the total population is substantial. In New Zealand, this gap has been subdivided further by socioeconomic position. At each social level, Maoris have higher mortality than Europeans at, notionally, the same level. In the USA also, Native Americans and Native Alaskans have lower life expectancy than the total population.

Social gradient in poorer countries

A social gradient in health is observed in many poorer countries. Regrettably, few countries have data systems that allow national data to be disaggregated by some measure of social position; this is especially true for adult mortality. Demographic and health surveys yield data for infant and child deaths (figure 2). In each country, the higher the socioeconomic quintile of the household, the lower the rate of child mortality. The result is a gradient, not simply that the poor have high mortality and everyone else is better off.

Although data for adult mortality by social position are sparse in developing countries, data from Matlab in Bangladesh show clearly that increased education is associated with reduced adult mortality. Similarly, in Chile there are marked differences in adult survival according to education. At age 20 years, women with 13 or more years of education can expect, on average, to live to 72 years of age compared with about 60 years for women with 1–8 years of education.

In the transition economies of central and eastern Europe and the former Soviet Union, the social gradient is clear. In the Russian Federation, to take one example, we used a survey method to reconstruct mortality data for men by education. In a population survey we asked whether husbands and brothers were still alive and, if dead, when they died. Figure 3 shows that those with little education had higher mortality than those with university education, and the gap has been growing every year since the collapse of the Soviet Union.

Inequalities between countries

Life expectancy for some countries is shown in table 2, along with gross domestic product (GDP) adjusted for purchasing power. The range of life expectancy is staggeringly large: from 32·5 years (both sexes) in Swaziland to 82 years in Japan. This gap in life expectancy has been growing. Figure 4 has much to encourage us and much to depress.

In the 1970s, life expectancy in central and eastern Europe and the Soviet Union was 69, ie, 2·6 years behind the high-income OECD countries. 30 years later, the life expectancy had declined to 68·1 years, now 10·7 years behind the OECD countries. At the other end of the life expectancy scale is sub-Saharan Africa where overall life expectancy increased by 0·3 years at a time when it increased by 7·2 in the richest countries. This small increase masks dramatic
declines in many African countries: from 49 to less than 33 in Swaziland; from 50 to 36 in Lesotho; from around 56 to nearly 37 in Zimbabwe.

Some of this decline is due to the terrible toll of HIV/AIDS. Stephen Lewis cries in anguish that we cannot consider AIDS in Africa without considering the state of women and their special vulnerability to rape and sexual violence, early and forced marriage, and lack of access to education, economic and earning power, and rights to own and inherit land or property. My statement at the beginning of this lecture that the avoidable deaths of people in poorer countries has to do with the way we organise our affairs in society has no better illustration than the link of sex inequality to the AIDS epidemic in various parts of the world, especially Africa.

Similarly, I do not think we can understand the lack of improvement, even decline, in the countries of central and eastern Europe and the former Soviet Union without considering the opportunity of people to lead flourishing lives in the sense that I am using the term: autonomy and social participation.

Inequalities in health are not inevitable

Before diving into the question of explanations of inequalities in health and, hence, what we could do about them, I should make clear that they are not inevitable. Starting first with inequalities among countries, there is nothing inevitable about the data in figure 4. The rapid health improvements in some countries and the lack of improvement in others suggest that changes in social and environmental conditions, and in public health and basic medical care, could do much to change things for the better.

But what of the social gradient in health within countries—is that not inevitable? Social hierarchies are inevitable. Whether or not we could imagine a society without a hierarchy, we would need to search hard to find it. Hierarchies might be inevitable but the health gradient linked to hierarchies is less so. Simple observation shows that the size of the difference in health between top and bottom (as one measure of the size of the gradient) varies within a society over time and among societies.

Figure 3 showed that the gap in expected survival between those with university education and those with little education grew in Russia during the years since the collapse of the Soviet Union. In England and Wales, the gap in male life expectancy between bottom and top social classes grew from 5·5 years to 9·5 years in the space of 20 years (between 1972–76 and 1992–96), and then narrowed slightly.

Similarly, we see differences in the size of the socioeconomic gaps among countries. Figure 5 shows that the gap in mortality between men in manual and non-manual occupations varies among nine countries in Europe. Notably, the gap in Sweden is one of the smallest. The same study showed that relative differences varied somewhat differently. Relative differences will depend on the size of the denominator as well as the numerator. In Sweden the mortality rate in non-manual occupations is low and the relative gap is large. The absolute difference is, however, quite small—consistent with what might be expected if Sweden’s social democratic policies are leading to smaller inequalities in society.

We need not, then, accept the present size of the social gradient in health as fixed. If it can change, and we can understand why, action is possible to reduce it.

Poverty: lack of money and more

I have set myself the task of trying to achieve a unifying explanation for health inequalities that takes in both the
disastrously poor health (life expectancy below 40 years) of some extremely poor countries and the social gradient in health that we see in rich and poor countries alike. I might seem to have a steep hill to climb.

Poverty is widespread: 2·5 billion people, 40% of the world’s population, live on less than US$2 a day. That they have poor health as a result is not difficult to comprehend. The Preston curves show a clear relation between income of a country and life expectancy (figure 6).\(^{39,40}\) The Millennium Development Goals comprehend. The Preston curves show a clear relation between income of a country and life expectancy (table 2). Taking the USA as an example, we see that it is the richest country (apart from Luxembourg) but has similar life expectancy, for men, to Costa Rica or Cuba. Russia has a GDP considerably higher than Sri Lanka but with a considerably shorter male life expectancy.

The diseases that keep life expectancy low in Russia, and keep the USA lower than other rich countries, are not those that we usually associate with poverty. Excess mortality is from non-communicable disease and violent deaths. Table 1 shows that Australian Aborigines and Torres Strait Islanders have a life expectancy about 17 years shorter than the average for Australians. But their infant mortality rates are low at 15 per 1000 livebirths.\(^{49}\) The Kibera resident does not have these advantages. In the civil service has the material conditions for good health. If he or she becomes a parent, the chances of their baby dying before the age of 1 year is about 6·5 per 1000 livebirths.\(^{49}\) The Kibera resident does not have these material conditions for health: infant mortality is probably closer to 200 per 1000 livebirths. But both low-grade civil servant and slum dweller lack control over their lives; they do not have the opportunity to lead lives they have reason to value. The precise content of those lives will depend on whatever the society of the day deems necessary. This idea comes from the economist and ethicist Adam Smith. The linking idea is that people’s capability to lead a life they value will be determined by social conditions.

This richer understanding of poverty allows us then to approach the social gradient in health, and poverty and health, with the same framework. Social conditions will determine the degree of limitation on freedom or autonomy. The greater the limitation, the worse the health. Improvement of material conditions and basic services explain why the civil servant has better health than the Kenyan slum dweller. In both cases, however, low social position means decreased opportunity, empowerment, and security.

A second phenomenon, in addition to seeing social disadvantage as lack of empowerment, makes the search for a unifying explanation of health inequalities more feasible. The major burden of disease worldwide is non-communicable disease and injury and violent deaths.\(^{26}\) In the poor countries of sub-Saharan Africa, the burden of communicable disease matches that of non-communicable disease and injury. But in every other region of the world, non-communicable diseases dominate. A reasonable

---

Circles have diameter proportional to population size. GDP per head is in purchasing power parity dollars. Source: Deaton.\(^{41}\)
starting position is that the causes of coronary heart disease or specific cancers will be the same wherever they might be. Causes that apply in rich countries where there has been much research will probably apply to the same diseases in poorer countries, where there has been less research.

Armed with a richer understanding of poverty and the realisation that, increasingly, we need to explain the occurrence of the same disease, we can now turn to the explanatory framework. I want to start by using development economics as an analogy for reduction in health inequalities and then argue that it is more than an analogy.

Nicholas Stern, former Chief Economist at the World Bank, and colleagues argue strongly that development in poor countries rests on two pillars: economic growth and empowerment. The factors necessary for economic growth, such as a favourable investment climate, are indeed important. But the effect of growth on poverty, in all its dimensions including health and income, will be far more powerful if it comes hand-in-hand with empowerment of people and communities. Empowerment is both a means to social development and an end in itself if it equates with leading a life one values.

The analogy with health is that we can think of improvement in health of disadvantaged people as built on two intertwining pillars: material conditions for good health, and control of life circumstances or empowerment. In the first category come food, water, sanitation, provision of medical and public health services; in richer countries these will include, among other things, availability of healthy food, opportunities for exercise, and crime-free neighbourhoods. The second pillar is empowerment. Importantly, empowerment could act at the individual level or at the level of the community. As I shall describe below, one way in which empowerment can operate is that control over life circumstances reduces chronic stress and has favourable biological effects. Empowerment at the community level might also be important as a means of securing resources for health. For example, Simon Szreter has made the case that in 19th century England, collective efficacy of communities helped secure access to clean water supplies.

The two-pillar (growth and empowerment) model of development could function as more than an analogy. Development, in the sense of relief of poverty, will be important for improvement of health in poor countries. Empowerment might then have an important effect on health through its effect on relief of poverty, as well as more direct effects. Amartya Sen argues that economic growth leads to an improvement in health provided that it is set to increase by 43% in Italy and 54% in Japan between 2000 and 2030. Yet, in many countries at intermediate stages of development, the projected rate of growth of the ageing population between 2000 and 2030 is much more rapid; for example, 174% increase in India, 227% increase in Mexico, and 277% increase in Malaysia. Inequalities in health continue in these older age groups. In the English Longitudinal Study of Ageing (ELSA) the onset of disease, disability, and poor cognition happened about 15 years later in people of high social position than in those of lower social position.

Control and social engagement as contributors to inequalities in health

I use control and social engagement as an organising principle, a way of thinking, about human needs that might relate to health on the one hand and the nature of our social arrangements on the other. They are, though, more than an organising principle since there is direct evidence to support them.

My group studied control, initially, in the workplace. The context was the Whitehall II study of British civil servants in which the lower the position in the occupational hierarchy the higher the risk of coronary heart disease and other ailments. The old idea that managers at the top of the hierarchy are under more stress than people below them has been replaced by two
more explanatory models of work stress. The first, the demand control model, posits that stress at work is not caused by how much demand there is, but how much control there is in relation to demand. The second suggests that imbalance between efforts and rewards is the determinant of chronic stress. As evolved beings, we are social animals. Part of living in society is expectation of reciprocal rewards—reward in return for effort expended, which is part of what I mean by full social engagement.

We used both of these models in the Whitehall II study and showed that each was related to coronary heart disease risk independent of the other. A review of the evidence showed that there was a high degree of consistency, at least for the control dimension of the demand control model, from other studies. For example, a recent study from the Netherlands showed that beliefs about personal control over life were related to increased risk of coronary heart disease. As in the Whitehall II study, lack of control was a contributor to the social gradient in coronary heart disease over and above the contribution of the classic risk factors.

There are ways of depriving people of control over their lives other than in the workplace. In Whitehall II, we also asked people a simple question about how much control they had at home. Women who had less control at home had higher risk of heart disease than women with more control. We had similar findings for mental illness.

We have had a programme of work investigating the high rates of morbidity and mortality in the countries of central and eastern Europe and the former Soviet Union, of which figure 3 is but one example. In the Czech Republic, as in Whitehall II, low control at work was associated with risk of myocardial infarction and contributed to the social gradient in occurrence of myocardial infarction. Psychosocial factors at work were also related to depression in the Czech Republic, Poland, and Russia. We extended the idea of low control over life circumstances beyond the workplace. In a series of cross-sectional studies, we showed that low perceived control was related to poor health. These studies have the drawback that both the predictor (low control) and the outcome (poor health or mental illness) are based on self-reports. There is, then, the possibility simply of biased reporting or contamination of predictor and outcome. In an ecological study, in seven central and eastern European countries, we showed that mean rates of control of a population sample were related to mortality rates of the country from which the sample was drawn. Contamination of subjectively reported measures is not an issue in this ecological study.

These studies from central and eastern Europe suggest that whole populations can be, more or less, deprived of control over their lives. These communities suffered during the last two decades of the communist period and, in Russia in particular, they suffered when communism and many social institutions collapsed, real incomes declined by more than half, and there was a dramatic increase in inequality in society. The other important human need, after autonomy or control, is to be socially engaged. Imbalance between efforts and rewards is part of not having appropriate social reciprocity. I suggest that self-esteem and the esteem of others is part of social engagement. Adam Smith pointed to the importance of having whatever was necessary for taking your place in public without shame. If I am to include all of these under social engagement it might sound a little nebulous. Two strands of evidence more directly support the link between social engagement and health: social supports and social capital.

Lisa Berkman, in a range of studies and review of the published work, showed that participation in social networks and having a range of social ties is important for health. Sheldon Cohen has contributed to and reviewed this literature with similarly strong conclusions. Marriage is one obvious domain in which support might be offered or denied. There has been much debate as to the causal interpretation of the health advantage of those who are married. Does health lead to marriage or marriage to health? I do not propose to reopen that debate here. It is of interest, however, that in Hungary and the Czech Republic the rise in mortality during the last two decades of the communist period was more rapid in unmarried men than in married. The increasing disadvantage of the unmarried state was more marked in men than in women, thus adding fuel to the speculation that marriage is more supportive for men than for women.

Taking social networks and supports to the level of the community leads to ideas of social capital—the idea that some communities are marked out by cohesiveness and trust. The evidence supporting the links between the social capital of a community and health is suggestive. Kawachi has made the idea operational and shown links between social capital and health. Diez-Roux has shown that characteristics of areas affect people’s health over and above the socioeconomic characteristics of the individuals who live there. We have contributed to this literature by showing that these area characteristics might be part of social capital.

My own speculation is that the remarkably good health of Japan could relate to the social cohesion of that society. Similarly, the good health of relatively poor populations such as those of Kerala and Sri Lanka might be attributed to cohesion and social inclusion—particularly of women.

**Pathways linking autonomy and social engagement to health**

One set of pathways are those linking autonomy and engagement to resources that lead to better health. Szreter finds no mystery in the link between social capital and health in Victorian England. It led to community action to provide clean water supplies. If social inclusion means
that more people are involved in education, they will benefit from all the economic, social, and psychological benefits that education can bring. As stated above, an approach to controlling HIV/AIDS in southern Africa that ignores the gender disadvantage of women will have little chance of success.

At a more general level, if empowerment is a key strategy for economic and social development then apart from any direct effect of empowerment on health there will be the indirect benefits that accrue from economic and social development of the whole society.

Conversely, if we see autonomy—leading the life one values—as central then resources are important in creating autonomy and social engagement. For example, having a ready supply of potable water, adequate shelter, and bathroom facilities makes leading a life one values more of a possibility.

A second set of pathways relate to the familiar risk factors for chronic disease. There are two questions that relate to my theme: to what extent do the classic risk factors account for the social gradient in disease occurrence; and might differences in health behaviours be one way that autonomy and social engagement change risk of disease?

In the first Whitehall study, a combination of smoking, plasma cholesterol, blood pressure, being overweight, and lack of physical activity accounted for under a third of the social gradient in coronary heart disease mortality. Some estimates put the contribution of smoking higher than that, but these are based on indirect measures that use lung cancer as a proxy measure for smoking and are higher than some other estimates using proxy measures. Whatever the precise contribution of these risk factors to the social gradient, they are important. Smoking is now linked with social disadvantage in the developing world as well.

Similarly for obesity, we know that, particularly for women, there is a clear inverse association with socioeconomic position. This association is now emerging in developing countries. The relation of obesity to education, as a measure of socioeconomic position, is shown in figure 7, with countries classified by degrees of economic development. Above a GNP per head of about $2990 (so-called upper middle-income economies), the higher the education the lower the obesity rate.

We need to ask, then, why there should be social gradients in important risk factors for chronic disease. This is not well understood but autonomy and social engagement might be important. The point has been well made that women who are socially disadvantaged and have little opportunity to control their lives or gain personal fulfilment might have little motivation to refrain from smoking.

A third type of pathway linking autonomy and engagement, or human flourishing, to health is through chronic stress pathways. Sapolsky has shown the plausibility of stress mechanisms linking social circumstances and status to health in non-human primates. Both the hypothalamic pituitary adrenal axis and sympatho-adreno-medullary axes are important. Sapolsky and others have shown that low-status animals have higher cortisol levels than high-status animals. The strength of this link between low status and cortisol varies across animal species; the more frequently low status is associated with being on the receiving end of stressful encounters the stronger the link between low status and cortisol.

In the Whitehall II study we were particularly interested in two elements of stress pathways linking low social position to increased risk of cardiovascular disease: plasma fibrinogen as an inflammatory marker and the metabolic syndrome. Both are linked to low social position. We have also shown that psychosocial factors are linked to the metabolic syndrome. Figure 8, from the Whitehall II study, shows that the more frequently people reported that their jobs were high strain (low control, high demands, little support) the greater the likelihood of having the metabolic syndrome. Likely mechanisms linking psychosocial factors to the metabolic syndrome are both the autonomic nervous system and hypothalamic pituitary adrenal axis.

My colleague, Andrew Steptoe, studies these psychobiological pathways in the laboratory. He shows the plausibility of linking stressful stimuli to cardiovascular, endocrine, and immune responses, and that these
responses differ according to socioeconomic position. One interesting finding was that it was not so much the height of the biological stress response that differed by socioeconomic position, but that low-grade civil servants had slower rates of biological recovery after stress.

Medical care?

I have said little about medical care. There is no question that part of improving health in poorer countries, as in richer, is the provision of comprehensive primary care. In a well-organised society there should be universal access to high quality medical care. The whole principle of the UK National Health Service is universal provision and that seems a principle worth exporting. In poorer countries of the world, as in some richer ones, attempts at universal provision do not guarantee universal access. A study in 21 low-income and middle-income countries showed that government expenditure on healthcare favoured, selectively, those of higher incomes (figure 9). In 15 of the countries, people in the top quintile of income obtained the greatest benefit; in only four did people in the bottom quintile of income benefit most; and in two the benefit from government health expenditure was equally shared between top and bottom income groups.

Gwatkin and colleagues make the point that the health of the poor has more to do with their social and environmental circumstances than with their lack of healthcare. But, since $380 billion is spent every year on health services in low-income and middle-income countries, it is worth asking whether there are ways to ensure that the expenditure benefits those who need it most—the people at the bottom of the income scale. These people want policies to be not only pro-poor in intent but also in effect.

Among rich countries, there is little relation between expenditure on medical care and health. We run the English Longitudinal Study of Ageing (ELSA), which was set up along similar lines to an existing US study, the Health and Retirement Study (HRS). Given that the USA spends $5274 per head on medical care, and the UK $2164 (adjusted for purchasing power), we were interested in comparing health and health inequalities in the two populations. We compared white men and women, aged 55–64. For each of seven common conditions there is a similar social gradient in health in the two countries, but for each condition more Americans have it than English people. Figure 10 shows the prevalence rates for three of these conditions. One possibility is that Americans have not more illness but more doctors. Greater recognition or recall of illness is not the most likely explanation, however, since in the USA glycosylated haemoglobin was higher, as were levels of C-reactive protein and fibrinogen; levels of high-density lipoprotein cholesterol were lower. Each of these biological markers points to more illness in the USA.

Smoking rates were similar in the USA and England, and alcohol consumption was higher among the English. The prevalence of obesity was about ten percentage points higher in the USA than in England and obesity is likely to be an important factor, particularly for the higher prevalence of diabetes. Although adjusting for the differences in obesity did not abolish the American disadvantage, these were cross-sectional data and we could not look at the cumulative effects of obesity. The higher rate of reported illness is consistent with the higher age-specific mortality rates of the USA compared with the UK in the age range 0–74 years. Interestingly, the USA has lower mortality rates than the UK in those over 74. We do not have the answer to the conundrum posed by the higher rates of illness in the USA but I would speculate that it has, in part, to do with the circumstances in which people live and work—the social determinants of health.

Creating freedom and empowerment

If empowerment is so important for health, how does it arise? Stern conceives of three classes of influence. First are individual endowments: assets and human capital. Second are external constraints that come from the context of family, community (including caste and religion), society, and systems of governance, all of which shape people’s lives. Third, individuals have internal constraints.
on their actions associated with their preferences and perceptions of their role. These classes of influence might be inter-related.

One telling example of societal determinants of empowerment comes from a study of 11–12-year-old children in India.\(^{109}\) High-caste and low-caste children were given mazes to solve. Despite the high-caste children having higher levels of parental education, the two groups of children did identically on the tests. The tests were then repeated, on different groups, but this time attention was drawn publicly to the caste of the children. Under these circumstances, the lower-caste children did substantially worse. The researchers put this decrement in performance down to an expectation, borne of experience, that lower-caste children would be treated unfairly—it was part of their powerlessness. Confirmation for this speculation was provided by randomly rewarding children, rather than having the decision apparently made by the investigator. Once the rewards were deemed to be fair, the performance of the lower-caste children again matched that of the higher caste.

Power, then, is key.\(^{110}\) Control, autonomy, and freedoms might sound like psychological properties of the individual. As the Stern framework makes clear, however, this is a partial view. Power relations in society, as they operate through social institutions and the opportunities afforded to those in relatively disadvantaged positions, are the social causes of degrees of empowerment. Interestingly, democracy, which should allow more of us some semblance of control, seems to be good for health even after taking other social conditions into account.\(^{111}\)

An important caution applies to the idea of freedom. In the sense used by Sen, and here, it does not imply privileging the rights of some individuals at the expense of the well-being of others. Human rights can be taken as implying an obligation on society to do what is necessary to bring about the important freedoms that those rights embody.\(^{112}\)

**Research as a guide to action**

A mark of our civilisation is that we value scientific understanding for its own sake. The Enlightenment brought with it the idea that critical questioning was a better way to the truth than received wisdom. Hence we prize research and scholarship because they enrich us culturally. It is not against this spirit that we might want to apply our knowledge. As physicians we seek not only to understand, but also to make things better. So, too, in public health but the sphere of action is collective rather than individual.\(^{113}\)

We do not seek to improve public health simply by informing individuals of health risks. This is fairly obvious when the health risk comes from the environment. Faced with impure water in a village, we understand that asking each villager to drink expensive bottled water is probably a less effective strategy than piping clean water to the village. This idea might be less obvious when it comes to behaviours related to chronic disease, but the same insights apply. Individuals choose to drink, smoke, or eat more calories than they consume in physical activity, but their choices are influenced by the environment.

The history of smoking control shows the importance of social action. It has a long history. WHO’s Framework Convention on Tobacco Control adopted by the World Health Assembly in 2003 is a landmark achievement in public health.\(^{114}\) Its basic premise is the necessity of governments to be involved in reduction of smoking by individuals.

I have been concerned with the example of alcohol. Evidence shows that the prevalence of heavy drinking is linked to the overall wetness of a population—the total amount of alcohol consumed.\(^{115,116}\) Key drivers of alcohol consumption are price and availability.\(^{117}\) Policies to reduce alcohol-related illness, therefore, should deal with price and availability not head off in the opposite direction.\(^{118}\)

Social action is as important when it comes to autonomy and opportunities for full social engagement. I was distressed to learn that, at a counselling session for workers who were about to lose their jobs, they were told that Professor Marmot’s research shows that control over your own lives is good for health. Now that they would not have to come into work every day these about-to-be unemployed individuals could look forward to taking control over their lives.

This, of course, is a caricature of the research findings, even a travesty. Individuals’ opportunities to control their lives, to be empowered, and to participate fully in society are heavily determined by the way we organise our affairs in society. An excellent review considered the ability of empowerment to improve health.\(^{119}\) It provides encouragement that social change based on insight and understanding can lead to greater empowerment. The review cautions that evidence for the direct effect of improvements in empowerment on health is more limited.

It was precisely to marshal the evidence on social action to improve health that the WHO set up the Commission on Social Determinants of Health. We have set up nine “knowledge networks”: early child development, employment conditions, social exclusion, women and gender equity, urban settlements, globalisation, health systems, priority public health conditions, and a cross-cutting network on measurement and evidence. We have a number of other mechanisms for generating the knowledge needed for action: distilling the experience of countries that have been taking action, working with civil society groups, engaging with other organisations.\(^{20}\) The Commission is due to report in 2008. Its driving principle is social justice: to reduce unfair differences in health between social groups within a country and between countries. A key mechanism is evidence-based policy. Evidence itself is not enough. There has to be the desire, the political will, for change. Given that will—a big given but I am an optimist—the evidence of what works will be a great help.
The physician and social change
Rudolph Virchow has featured many times in these Lectures. Paul Nurse, for example, quotes Virchow’s understanding of cells: “that every animal appears as a sum of vital units, each of which bears in itself the complete characteristics of life”. My first contact with Virchow’s writing was in relation to his studies of the blood and blood vessels that are important still for our understanding of the pathology of atherosclerosis.

As well as being a scientist who contributed so much to our understanding of pathology, Virchow was also concerned with improving the public health. He wrote: “If medicine is to fulfil her great task, then she must enter the political and social life. Do we not always find the diseases of the populace traceable to defects in society?” He went on: “If disease is an expression of individual life under unfavourable circumstances, then epidemics must be indicative of mass disturbances”. Since disease so often results from poverty, he said, then physicians are the “natural attorneys of the poor”, and social problems should largely be solved by them.

I have made the case that a richer understanding of poverty, based on control and social engagement, links the social gradient in health, and poverty and health. We should focus not only on extremes of income poverty but on the opportunity, empowerment, security, and dignity that disadvantaged people want in rich and poor countries alike.

For Virchow, then, it was not biology or society, but both. We need biological understanding of disease but we need, too, understanding of how society influences biology, in order to change disease risk. This social understanding is central to the process of change to reduce the burden of disease.

As physicians we need to be the natural attorneys of the disadvantaged. The Commission on Social Determinants of Health was launched in Chile. It seemed appropriate, then and now, to quote Chile’s Pablo Neruda and invite you to: “rise up with me…against poverty, that disadvantaged people want in rich and poor countries alike.

For Virchow, then, it was not biology or society, but both. We need biological understanding of disease but we need, too, understanding of how society influences biology, in order to change disease risk. This social understanding is central to the process of change to reduce the burden of disease.

As physicians we need to be the natural attorneys of the disadvantaged. The Commission on Social Determinants of Health was launched in Chile. It seemed appropriate, then and now, to quote Chile’s Pablo Neruda and invite you to: “rise up with me...against the organisation of misery.”
